

## GATEWAY FOR USING NON-IP DIGITAL PBX TELEPHONE HANDSETS WITH AN IP CALL CONTROLLER

This application claims priority from United States patent application 60/258,464 filed  
5. December 27, 2000.

### Background

Early telephone systems had a separate circuit from the central office to each  
telephone and a switchboard with plugs and wires in the central office for a person to make  
10 connections. Automated switches replaced the plugs and wires operated by a human. Then  
some of the automated switching functions were moved upstream into private equipment in  
company offices to save the cost of requiring a separate line from each telephone to the  
central office. Because the central office was called an "exchange", the remote switch was  
called a "private branch exchange", or PBX. At first, the PBX merely performed switching  
15 functions. Then, as additional functions were invented for business telephones, such as  
hold, transfer, conference, indicator lights, and displays, what was merely a switch became  
what we refer to here as a "call controller". A KTS (Key Telephone System) is a simpler and  
less expensive form of such a call controller. Within this document, the term "call controller"  
is used to describe both such PBX and KTS devices as well as a newer form of call  
20 controller that uses packet switching on a packet switched network, preferably a network  
running Internet Protocol (IP), discussed further below. Although the new IP call controller is  
"private", it is not in any sense a "branch exchange", so the term IP-PBX, while it is  
commonly used, is misdescriptive.

The handsets that are used with a PBX or a KTS support many additional features  
25 that a standard analog telephone for use with the public network can not support. Although  
there are differences in functionality between a PBX and a KTS, the handsets for use with  
either are essentially the same. When this document refers to a PBX telephone handset, it  
means a handset with additional features for use with a PBX or with a KTS that supports  
those features. Likewise, when this document refers to PBX equipment, unless the context  
30 requires otherwise, it means PBX or KTS equipment.

Standard PBX (or KTS) equipment for the last 30 years has used digital  
communications between the PBX and the telephone handset to exchange the various call  
control signals between the PBX call controller and the digital handset. Within the PBX, in

order for a circuit to handle control signaling and many telephone call voice signals at once, time division multiplexing (TDM) was developed. In this method, each hundredth of a second is divided into many much smaller time slots and the time slots are allocated sequentially among many circuits. Each circuit receives a high enough percentage of each  
5 hundredth of a second of time to produce a voice quality connection for reception by a human.

Although digital signaling between each handset and the PBX with TDM multiplexing in the PBX has become universally adopted by all telephone equipment manufacturers, there are no standards. Consequently, the handset of one manufacturer will not operate  
10 with the PBX of another manufacturer. However, as publicly regulated monopolies, telephone companies began to offer similar call control functions from their central offices with digital call control signaling from call controllers running public signaling protocols called "Centrex" systems. Centrex systems and PBX systems all used "circuit switched" networks where a single circuit, although it may be time division multiplexed, is established between  
15 each pair of telephones in communication with each other and those telephones use 100 percent of that circuit, even when neither party is talking.

Economies of scale can be accomplished if the voice communications are merged with data communications, and further economies are achieved if the communications are sent via packet switched networks rather than circuit switched networks. A packet switched  
20 network can merge packets from many different origins destined for many different destinations into a single "channel" and then separately switch them to different directions at a subsequent point in their journey, as opposed to a circuit switched PBX (or KTS) which switches calls through the creation of physical electronic circuits and uses time division multiplexing (TDM) on a local area bus.

25 Attempts to merge voice communications and data communications over packet switched networks did not achieve market acceptance until implementation of the global computer network based on Internet Protocol (IP). IP telephony is revolutionizing the telecom industry with promises of the following benefits (among others):

1. Eliminating distance sensitivity in pricing and telecom features. A call from  
30 London to Seattle can cost the same and provide the same features as a call between two offices on the same floor.

2. Easing the development and deployment of intelligent features such as computer-telephone integration, "reach me" and "personal assistant" services, and unified messaging.

3. Reducing the cost of telephone systems by leveraging the economies of scale that come from putting voice and data traffic on a single data network rather than two disparate and separately maintained networks (one for voice, one for data).

5 These benefits of IP telephony are typically delivered through a proprietary IP call controller (often misdescriptively called an "IP-PBX" -- Private Branch Exchange -- by analogy to a traditional PBX) using packet switching on a data network. Some of the same benefits can also be provided by a public IP call controller, an IP Centrex system.

10 To obtain some of the benefits of using the global IP network for telephone communications, as shown in Figure 3, PBX manufacturers have been adding an internet protocol interface on the trunk side of the PBX 51 so that, in addition to sending out calls over the public switched telephone network (PSTN) 15, they can also send calls via Voice over IP (VoIP) on the Internet 23. However, further benefits can be achieved by communicating between the handsets and the call controller via IP on a data network using IP handsets and IP call controllers (IP-PBXs).

15 Most existing circuit switched PBXs (and KTSs) support desktop telephone handsets which use a variety of proprietary digital signaling methods to deliver enhanced features such as an LCD call status display, multiple line appearances, various indicator lamps, and intelligent "feature buttons". Contemporary IP PBX systems do not support these handsets but instead support proprietary IP digital telephone handsets. The IP digital telephone  
20 handsets connect directly to an IP network and therefore require fairly intelligent IP circuitry in the handset, which makes them rather expensive compared to the digital telephones employed by a typical circuit PBX. Most IP PBX's also support the attachment of standard analog telephones via various gateway devices. This reduces the cost of the handsets, but analog telephones do not support the advanced features which a typical business user  
25 expects -- such as LCD display and indicator lights. So the trade-off for users of IP telephony is: a) pay more for IP phones with lots of features, or b) settle for less expensive analog phones with gateways but fewer features.

A hybrid has been developed that allows companies to use their existing handsets and traditional PBX equipment but carry the communications between the two across an IP  
30 network so that the handsets and PBX can be located remotely from each other while using the IP network to achieve a highly effective low cost connection. As shown in Figure 4, this system requires a gateway 62 that places the PBX signals into packets and provides IP headers for those packets so they can be transmitted on an IP network. Similarly, the handsets 10 are coupled to a remote access interface 61 that receives packets from the

PBX, extracts the voice data and feature signaling data from each packet, and forwards the resulting PBX type data to the appropriate handset. Likewise, it receives signaling data from each handset and encapsulates the data into IP packets, adds a header to each packet, and sends them on the network to the gateway where the data is decapsulated.

5           When voice communications (or other real time communications) are sent over an IP network, the packets must be given precedence over packets that are not sensitive to real time delivery, such as computer data packets, to avoid problems of perceptible time delays and "jitter" which is a disruption in voice quality resulting from otherwise imperceptible time delays. Therefore, voice communications are routed over IP network connections where  
10       such precedence can be managed over each link in the network.

### Summary

This document discloses a gateway device **11** that enables a cluster of less-expensive but feature-rich "traditional" digital non-IP PBX telephones to operate with a new  
15       IP call controller (IP PBX). These gateway devices can also be made to support the existing installed base of proprietary digital telephones such that a current PBX owner can retain their desktop telephones while installing a new IP PBX or connecting to a carrier's IP Centrex service. This represents a unique new architecture for IP telephony in that traditional digital business telephones are connected to a purely packet-switched telephony  
20       network through a cluster controller or "Handset Gateway" as shown in Figure 1A.

While Figure 1A shows a Handset Gateway connected to a LAN (Local Area network), the Handset Gateway can also be combined with a DSL (Digital Subscriber Line) modem or other broadband connection to an IP network to create a unique IAD (Integrated Access Device) supporting traditional digital business telephones on an IP Centrex service,  
25       as shown in Figure 1B.

It is important to note that in both cases, the traditional non-packet-switched digital business telephones are connected directly to a wholly packet switched voice communications service. This differs from the prior art which involves using IP packet links as transport links in a circuit-switched voice communications network.

30           In one aspect, the invention is a gateway for using non-IP digital PBX telephone handsets with an IP call controller. The gateway has one or more ports for coupling non-IP digital PBX telephone handsets to the gateway. It also has an IP port for coupling to an IP network device for communicating in Internet Protocol on an IP network. Inside the gateway device is a translator circuit that translates non-IP digital PBX telephone call control signals

received at a handset port into IP telephone call control signals for an IP telephone call controller and delivers them to the IP port. The same circuit or a parallel circuit also translates IP telephone call control signals received at the IP port from an IP telephone call controller into non-IP digital PBX telephone call control signals and delivers them to the one or more handset ports.

The gateway may be designed and built to work only with one particular IP call controller protocol and one particular non-IP digital PBX telephone handset protocol. However, in the preferred embodiments, it is programmable so that it can be programmed to work with any of many different IP call controllers and any of many different non-IP digital PBX telephone handsets. Such programming may be done by coupling to the gateway a wire connected to a user interface device, such as a personal computer with a keyboard and monitor. The preferred method of programming is with IP communications through the IP port. The IP communications may come from a general-purpose computer operated by a human with a keyboard and monitor or it may come from any other computer on the IP network that downloads to the gateway a set of data parameters or program instructions that cause the gateway to work with a selected IP telephone call controller and a selected set of non-IP digital PBX telephone handsets. The download of such parameters or instructions may happen automatically once an IP session is established between the gateway and an IP service.

Using the configuration circuits just described, the invention is also a method in a telephone IP gateway for programming the gateway to work with a particular IP telephone call controller. In this method, the gateway receives at an IP port a signal from an IP telephone call controller and, based on the signal, sends to a remote IP server via the IP port information identifying the call controller. Then, the gateway receives from the server programming information, such as data parameters or program instructions, which cause the gateway to work with the IP telephone call controller. The information identifying the call controller that is sent to the remote IP server may be the actual signal received from the call controller. Alternatively, the gateway may use a processor to analyze the signal, retrieve from a memory information identifying the call controller, and send that information to the remote IP server.

Analogously, the invention is also a method in a telephone IP gateway for programming the gateway to work with non-IP digital PBX telephone handsets. In this method, the gateway receives at a port for non-IP digital handsets a signal from a connected handset and, based on the signal, sends to a remote IP server via an IP port in the gateway information identifying the handset. Then, the gateway receives from the server

programming information for the gateway to cause the gateway to work with the handset. As described above, the method can be performed by passing to the server the actual signals received from the handset or by processing the signals in a processor to retrieve information identifying the handset from a memory in the gateway and forwarding that information to the  
5 server.

In another aspect, the invention is a method in such a gateway with enough "intelligence" to manage call control functions with the non-IP digital PBX handset which functions do not actually require a response from the IP call controller. For example, if a user of the handset wishes to put a call on hold, the gateway can send the appropriate  
10 signals to the handset to light a hold indicator and can cease passing voice signals to and from the handset for the call that has been placed on hold.

In a related aspect, the invention is a method for the gateway to implement a call control function by receiving from a non-IP digital telephone handset coupled to the gateway a command to perform a call control function and, in response, sending a call control signal  
15 to a second non-IP digital telephone handset coupled to the gateway. For example, the function may be the establishment of a voice connection between the first handset and a second handset with no communication sent via the IP port. Alternatively, the function may be the establishment of a telephone conference between a first handset and a second handset and one or more IP voice streams entering the gateway from the IP network.

In another aspect, the invention is a gateway for non-IP digital PBX telephone handsets that assigns an address for IP communications to each handset port to which a non-IP digital PBX telephone is coupled and registers each address for IP communications with the IP telephone call controller. This allows each telephone handset to be viewed by the controller as a separate device. The gateway itself becomes transparent to the call  
20 controller.  
25

While this transparency is preferred for enabling maximum functionality of each handset, there are other system management functions in which the IP telephone call controller communicates directly with the gateway, such as gateway registration and system status reporting. In this aspect, the invention is a gateway that includes a registration circuit  
30 the registers the gateway with the IP telephone call controller for such system management.

In another aspect, the invention is a gateway for coupling non-IP telephone handsets to an IP network that also includes sub-ports for coupling other IP devices to the IP network. In this aspect, the gateway includes a general purpose IP router for coupling one or more additional devices to the IP network in addition the handsets. In order for the handsets to

operate with sufficient voice quality communications, the IP packets going to and from the handset are given voice quality precedence over packets received at the one or more IP sub-ports.

5 In another aspect, the above-described gateway may be built as a plug-in card for an IP call controller as shown in Figure 1C. Although this prevents the IP call controller from being located remotely from the gateway as shown in Figures 1A and 1B, it presents economic advantages by allowing the gateway to be made at lower cost with lower cost connections between the gateway and the IP call controller.

10 In another aspect, the invention is a system wherein non-IP digital PBX telephone handsets are coupled to an IP telephone call controller in a public telephone network. The system includes an IP telephone call controller operating a public telephone network according to public IP call control protocols and coupled to the global IP network. There is also a gateway coupled to the global IP network at a location remote from the IP telephone call controller with one or more non-IP digital PBX telephone handsets coupled to the  
15 gateway via wires for carrying non-IP digital PBX telephone call control signaling between the handset and the gateway. As described above, the gateway has one or more protocol translating circuits that translate non-IP digital PBX call control signals received from a handset into IP call control signals according to the public IP call control protocols of the call controller. The same circuit or a parallel circuit also translates IP call control signals from the  
20 call controller into non-IP digital PBX call control signals for a handset coupled to the gateway. In this embodiment, the gateway preferably includes a general purpose IP router coupled to the IP port in the gateway and to one or more IP sub-ports in the gateway, and the router gives voice quality preference to IP packets going to or from the one or more telephone handsets over IP packets going to or from devices coupled to the IP sub-ports.

25 In another aspect, the invention is a system where one or more non-IP digital PBX telephone handsets are coupled to a proprietary IP telephone call controller in a private telephone network. In this aspect, the invention comprises a proprietary IP telephone call controller operating according to proprietary IP call control protocols coupled to the global IP network. Also coupled to the IP network is a gateway in a location remote from the call  
30 controller with one or more non-IP digital PBX telephone handsets coupled to the gateway via wires for carrying non-IP digital PBX telephone call control signaling between the handset and the gateway. As described above, the gateway has one or more protocol translating circuits that translate non-IP digital call control signals received from a handset into IP call control signals according to proprietary IP call control protocols of the call  
35 controller. In addition, the same circuit or a parallel circuit translates proprietary IP call

control signals from the call controller into non-IP digital call control signals for a handset coupled to the gateway. As described above, the gateway may include a general purpose IP router which gives voice quality preference to IP packets going to or from the one or more telephone handsets over IP packets going to or from other devices coupled to IP sub-ports in the gateway.

### Brief Description of the Drawings

Figure 1A shows the system configuration for use with a proprietary IP call controller.

Figure 1B shows the system configuration for use with a public Centrex IP call controller.

Figure 1C shows the system configuration where the gateway is a plug-in card in a proprietary call controller.

Figure 2 is a block diagram of the internal design of the handset gateway.

Figure 3 shows prior art, a proprietary PBX with a VoIP trunk.

Figure 4 shows prior art, a PBX connected to its matched handsets with an IP link where the PBX signaling is encapsulated in IP packets and then decapsulated upon receipt.

### Detailed Description

Figure 1A shows the gateway in a system where the gateway **11** is remote from the IP call controller **12**, coupled via an IP network **17**, which might be a LAN or WAN or the Internet. The system is coupled to the public switched telephone network (PSTN) **15** via a PSTN gateway **14**. IP telephone handsets **16** may be coupled to the network **17** and other network devices, such as new IP telephone handsets **13** or a computer **18** may be coupled to the network **17** via IP sub-ports in the gateway **11**.

As shown in Figure 1B, the gateway **11** might be configured to work with an IP Centrex service call controller **24** across any broadband IP network, including the Internet **23**.

As shown in Figure 1C, the gateway may be implemented as a card **40** which plugs into a slot in a proprietary IP call controller **42**. The traditional non-IP digital handsets **10** are connected via wires to the gateway card **40**. The IP call controller **42** is connected to an IP network **17** which may be connected to a PSTN gateway **14** for connection to the public switch telephone network **15**. The IP connection from the call controller to the PSTN

gateway can be internal to the call controller chassis and the PSTN gateway can be a plug-in card.

Refer to Figure 2, Handset Gateway Internal Design. Each traditional non-IP digital handset **10** is connected to the gateway through a Line Interface **31** which is preferably  
5 based on the existing generic digital handset interface developed and marketed by CITEL, assignee of this patent.

A single FPGA (field programmable gate array) device **32** is partitioned into a number of virtual line interface logic units **33**, one for each handset, and an aggregating FPGA **34** multiplexes all of the channels together before passing the control and audio information to  
10 the central processor **38**.

Discrete ROM **36** is used to store the loaded program which is run by the central processor **38**. For the preferred embodiment, the ROM is programmable and electronically erasable, such as flash memory, for storing the downloaded program. The gateway is initially shipped with a program in the ROM that, upon power-up, performs the following  
15 steps. First, it sends a set of signals to each handset port that is designed to produce a different response from each different proprietary handset that the gateway is intended to work with. Then, the signal that is received in response is processed and compared to data stored in the ROM to identify the type of handset on that port, if any, and this information is stored in the ROM. Next, the gateway waits for a hyper text transfer protocol (HTTP) query  
20 from a browser directed to the gateway's built-in IP address. Upon receipt of the query, the program displays in HTTP the handset information and a field where a user can enter an IP address of the IP call controller that the gateway is to work with. Then, the gateway sends a set of signals to the IP call controller and receives in response a set of signals that identifies the type of call controller. The gateway then sends via IP to a web server operated by the  
25 gateway vendor a set of information identifying the type of IP call controller and the type of handset on each port. The server then sends to the gateway the latest program designed to cause the gateway to work well with the controller and the handsets.

Discrete RAM **37** is required for buffering audio streams during packetization / depacketization by the processor **38**.

30 The central processor **38** performs the messaging translation, channel arbitration, and the interface to an IP call controller **12** via an Ethernet interface **39**.

DSP(s) **35** perform the audio compression / expansion (transcoding).

In operation, the Handset Gateway **11** connects to the IP network **17** and performs one IP telephony endpoint registration with the IP call controller per handset device. The

gateway can use DHCP (Dynamic Host Configuration Protocol) from a local server to obtain its IP address or addresses (one per attached handset device) or such IP address or addresses can be programmed into the gateway through a configuration interface. To the IP call controller **12**, each handset device connection appears as a discrete connection to the IP telephony network; while the gateway is transparent, appearing as a collection of IP telephones. To the digital non-IP handsets **10**, the gateway appears as a digital non-IP PBX or KTS. The gateway converts each handset's TDM signaling into packetized IP signaling. By sharing resources such as CPU, RAM, ROM, and DSP, the clustered gateway is much more economical than IP telephones **13**, where each phone has it's own CPU and related resources.

The Handset Gateway differs from prior technology in a number of ways.

1. Each digital handset appears as an endpoint to the IP Telephony network rather than the Gateway itself appearing as the end point. This is significant as it means that each digital handset is a discrete entity from the IP call controller perspective.
2. The digital handsets are connected to the IP call controller ("PBX") using the Gateway to translate the protocol stream for call control. The protocol is not simply encapsulated and transmitted from one point to another using an IP protocol, rather, the individual messages from the handsets are interpreted by the Gateway and translated to the protocol expected by the IP call controller, and messages from the IP call controller are likewise translated to the protocol for the handset.
3. The handset gateway uses a separate IP telephony session per phone, and a separate address for IP communications per phone.
4. The handset gateway 'pretends' to be a PBX or KTS and responds to the handset upon receipt of protocol messages sent by the digital handset.
5. The handset gateway will act as a router for other IP devices as shown in Figures 1A and 1B, giving priority to the connected digital phones.
6. In the prior art, programmable devices for connecting a handset to a PBX can be programmed only to connect to PBX handsets that are intended to work with that PBX. That is, in the prior art, the input protocol from the handset must match the output protocol to the PBX. By contrast, the Handset Gateway is separately programmable on the input and the output so it can match any handset to any IP call controller ("PBX").
7. The Handset Gateway registers itself with the IP PBX for management purposes.

The gateway can be programmed to handle various features and functions of the non-IP digital handsets rather than simply passing all signals from the handsets on to the IP call controller for handling. This is accomplished by changing the programs stored in the ROM. For example, if a signal is received from a handset specifying that a call is to be placed on hold, no signal needs to be sent to the IP call controller. Instead, the gateway can simply drop any voice signal packets that it receives from the IP call controller while the call is on hold and likewise drop any voice signal packets that it receives from the handset while the call is on hold. The gateway can send music or some other on-hold sounds in place of signals from the handset. The gateway can send a signal to the handset to turn on a hold indicator light.

Similarly, if a handset user wishes to add another handset on the gateway to a telephone conversation, no signal needs to be passed to the IP call controller. Instead, the signals can be interpreted by the gateway which can itself ring the second handset telephone. Once the connection is made, the gateway simply passes the voice signals from the IP call controller to both handsets, passes the voice signals from both handsets to the IP call controller, and passes the voice signals from each handset to the other. In this way, many features and functions of an IP call controller can be transferred to the gateway and implemented via programming at the gateway.

While the above description has described particular embodiments of the invention, other embodiments are possible. The invention is to be defined by the following claims without limitation based on the above description.
